[Title of the Invention]

SERVO CONTROL APPARATUS FOR OPTICAL DISC PLAYER

[Scope of claim for Patent]

5 [Claim 1] A servo control apparatus of an optical pickup for reading recorded information from a recording medium to generate a read signal, comprising:

an error signal extracting portion for extracting an error signal from said read signal, said error signal indicating a deviation from a servo target value of said optical pickup;

10 an equalizer including a phase compensator for equalizing said error signal by said phase compensator to generate a drive signal;

a driving portion for changing the servo position of said optical pickup in response to said drive signal;

15 a dropout detecting portion for extracting an envelope signal from said read signal to detect a dropout of said read signal; and

20 a controller for changing an equalization characteristics of said equalizer in accordance with an amplitude of the envelope signal in the portion of said dropout.

[Claim 2] A servo control apparatus according to claim 1, wherein said equalizer includes an integrator for integrating said error signal to generate an error integration signal and an adder for supplying an added signal of an error proportional signal which is proportional to said error signal and said error integration signal to said driving portion as said drive signal; wherein, when

the amplitude of an envelope signal in the portion of said dropout is less than a predetermined value, said controller performs at least one of decreasing the error proportional signal component in said drive signal and increasing the error integration signal 5 component to change said equalization characteristics.

[Claim 3] A servo control apparatus according to claim 2, comprising:

an integral value calculator for calculating an integral value of said error signal for each predetermined angular section 10 of rotation of a track on said recording medium;

an integral value storing portion for storing each of the integral values for one rotation of said recording medium;

a variation calculator for calculating a variation by comparing said integral value for an angular section of rotation 15 where said dropout occurred with a stored integral value for the identical angular section of rotation prior to the occurrence of the dropout;

wherein, when said variation is larger than a predetermined value, said controller performs at least one of decreasing the 20 error integrated signal component and increasing the error proportional signal component to change said equalization characteristics.

[Claim 4] A servo control apparatus of an optical pickup for reading recorded information from a recording medium to generate 25 a read signal, comprising:

an error signal extracting portion for extracting an error signal from said read signal, said error signal indicating a

deviation from a servo target value of said optical pickup;
an equalizer including a phase compensator for equalizing
said error signal by said phase compensator to generate a drive
signal;

5 a driving portion for changing the servo position of said
optical pickup in response to said drive signal;

 a dropout detecting portion for extracting an envelope signal
from said read signal to detect a dropout of said read signal;
and

10 a controller for changing an equalization characteristics
of said equalizer in response to an occurrence of said dropout.

[Claim 5] A servo control apparatus according to claim 4, wherein
said controller increases a phase margin in a predetermined
frequency range of said equalizer in response to an occurrence
15 of said dropout and decreases said phase margin in response to
the termination of said dropout.

[Claim 6] A servo control apparatus according to claim 4, wherein
said controller includes a timer for measuring the elapsed time
from the termination of said dropout and performs control for
20 changing said equalization characteristics of said equalizer based
on the output of said timer.

[Claim 7] A servo control apparatus according to claim 6, wherein
said controller changes said equalization characteristics of said
equalizer gradually in accordance with the elapsed time from the
25 termination of said dropout.

[Claim 8] A servo control apparatus according to any one of
claims 4 through 7, wherein said equalizer includes an integrator

for integrating said error signal to generate an error integration signal and an adder for supplying an added signal of an error proportional signal which is proportional to said error signal and said error integration signal to said driving portion as said drive signal; wherein said controller performs, during the occurrence of the dropout, at least one of decreasing the error proportional signal component in said drive signal and increasing the error integration signal component to change said equalization characteristics.

[Detailed Description of the Invention]

[Technical Field to which the Invention pertains]

The present invention relates to an optical pickup servo-control apparatus for use with an optical disc player.

5 [Prior Art]

Servo control is usually used to control an optical pickup for reading recorded information at a desired reading position for the purpose of achieving good reproduction performance in a player for optical discs, such as compact discs (CD) and digital versatile discs (DVD). An optical disc, however, usually contains defects, such as various kinds of flaws and contamination which occur during, for example, the manufacturing process or the use of the disc. Such defects impede a stable operation of the above-mentioned servo control.

15 Fig. 1 is a sectional view of an optical disc 1, showing the kinds of major defects which may occur. The optical disc 1 includes a protection layer 3, a reflective layer 4 which reflects the light beam emitted from the optical pickup, and a transparent substrate 5 made of a transparent material such as a plastic and
20 the like.

Referring to Fig. 1, a defect I is a flaw called an "interruption" in the reflective layer 4, caused in the manufacturing process of the disc. A defect II is a dirt called a "black dot" on the disc's surface or the transparent substrate
25 5. A defect III is a "fingerprint" of human fat on the disc surface
7. A defect IV is a flaw called a "scratch" on the disc surface
7.

The existence of such defects on a disc causes "dropout" in read signal (RF signal) generated in the optical pickup when the disc is played, and deteriorates the controllability of servo control including tracking control, focusing control, tilt control
5 and the like. A conventional method, for example, for preventing the adverse influence on servo control caused by such defect is to continue servo control by holding the control value of servo control, or the tracking error value, focus error value, or the like to the value before the defect was detected (hereinafter,
10 simply referred to as "pre-value hold").

[Problems to be solved by the Invention]

The servo control, however, becomes unstable when the dropout continues for a relatively long time or the dropout is of a burst type, because a bias or deviation value indicated by a value in
15 the pre-value-hold method (hereinafter, simply referred to as a "holdvalue") drifts too far from the actual bias value. For example, the drive signal for the optical pickup drastically fluctuates during the period when a dropout occurs, causing servo control instability as shown in Fig. 2. In addition, as the transient
20 phenomenon arises after termination of the dropout, servo control becomes unstable because the focus error signal is delayed in converging into a normal value, for example, as shown in Fig. 3. Therefore, the performance of servo control may be deteriorated or a gross deterioration in reproduction quality may be caused.

25 The defect such as a fingerprint or a black dot is usually formed over a plurality of tracks in the radial direction of the disc (i.e., in a certain range of a rotational angle of the disc).

Servo control also needs to be stabilized effectively against such defects.

Therefore, it is an object of the present invention to provide a servo control apparatus which is capable of performing stable 5 high-precision servo control during the period of time when a dropout occurs and after the termination of the dropout even if the dropout continues for a long time or the dropout is of a burst type.

It is another object of the present invention to provide 10 a servo control apparatus which has a high capability of dealing with various kinds of defects and of performing stable high-precision servo control.

[Measure taken to solve the problem]

According to the present invention, there is provided a servo 15 control apparatus of an optical pickup for reading recorded information from a recording medium to generate a read signal, which comprises an error signal extracting portion for extracting an error signal from the read signal, the error signal indicating a deviation from a servo target value of the optical pickup; an 20 equalizer including a phase compensator for equalizing the error signal by the phase compensator to generate a drive signal; a driving portion for changing the servo position of the optical pickup in response to the drive signal; a dropout detecting portion for extracting an envelope signal from the read signal to detect a 25 dropout of the read signal; and a controller for changing an equalization characteristics of the equalizer in accordance with an amplitude of the envelope signal in the portion of the dropout.

According to the present invention, there is provided a servo control apparatus of an optical pickup for reading recorded information from a recording medium to generate a read signal, which comprises an error signal extracting portion for extracting 5 an error signal from the read signal, the error signal indicating a deviation from a servo target value of the optical pickup; an equalizer including a phase compensator for equalizing the error signal by the phase compensator to generate a drive signal; a driving portion for changing the servo position of the optical pickup in 10 response to the drive signal; a dropout detecting portion for extracting an envelope signal from the read signal to detect a dropout of the read signal; and a controller for changing an equalization characteristics of the equalizer in response to an occurrence of the dropout.

15 [Embodiments of the Invention]

The embodiments of the present invention will be described in more detail with reference to the accompanying drawings. The same reference numerals refer to substantially similar elements throughout the drawings.

20 [First Embodiment]

Fig. 4 is a block diagram of the configuration of a servo control apparatus 10 of an optical disc player according to the present invention.

In Fig. 4, the optical disc 1 is rotated by a spindle motor 25 8. The spindle motor 8 is provided with an FG signal generator (not shown) for generating one pulse for each predetermined angle of spindle rotation. A generated FG pulse signal is supplied to

a controller 23.

An optical pickup 11 emits a laser light beam on the optical disc 1, receives the light beam reflected from the optical disc 1, and generates a signal in response to the amount of the received light. An optical detector 12 provided in the optical pickup 11 is, for example, a 4-partitioned optical detector consisting of four light-receiving elements. Each of the four light-receiving elements receives the light reflected from a beam spot (not shown), converts it into an electric signal to output as read signals RB₁-RB₄, respectively. The optical pickup 11 is further provided with a driving portion 19 comprising a tracking actuator for making the direction of an objective lens (not shown) or the reading point thereof, biased in the radial direction, and a focusing actuator for adjusting the focusing point of the beam spot.

With the above-mentioned configuration, the optical pickup 11 reads recorded information from the optical disc 1, and supplies the read signals RB₁- RB₄ to a signal processing circuit 15.

An RF amplifier is provided in the signal processing circuit 15. The RF amplifier amplifies the read signals RB₁- RB₄, and a tracking error signal TE and a focus error signal FE are extracted on the basis of the amplified read signals. More specifically, the signal processing circuit 15 generates the focus error signal FE using the read signals RB₁- RB₄. The focus error signal FE is a differential signal between two added signals obtained by adding read signals from the light-receiving elements diagonally opposing each other. The signal processing circuit 15 also generates a tracking error signal TE by the phase difference method using the

read signals RB₁- RB₄, for example. The tracking error signal TE and the focus error signal FE generated in the signal processing circuit 15 are supplied to a servo-equalizer (hereinafter, simply referred to as an equalizer) 17.

5 As described in detail below, the equalizer 17 is a circuit for compensating the amplitude and phase of error signals, such as the tracking error signal TE and the focus error signal FE generated in the signal processing circuit 15. More particularly, the equalizer 17 performs equalization processing on error signals
10 so as to have frequency characteristics suitable for servo control, and supplies the equalized signals to the driving portion 19 for the optical pickup 11 as drive signals TD and FD, respectively. The driving portion 19 generates actuator operating signals TDRV, FDRV based on the supplied drive signals TD and FD. The servo
15 control is performed by operating the actuator in the optical pickup 11.

Furthermore, according to the present invention, there is provided a dropout detecting portion 21 for receiving an RF read signal from the signal processing circuit 15 and for detecting defects formed on the optical disc 1, i.e., dropouts in the RF read signal; and a controller 23 for controlling the equalizer 17 in accordance with the dropout detection signal detected by the dropout detecting portion 21, the above-mentioned FG pulse signal, and signals from the signal processing circuit 15. The controller 23 is provided with a timer, an integral value storing portion for storing various data, such as the servo controlled value, the tracking error value, or the focus error value, and

an operation section for calculating the coefficient of the equalizer 17 and the like as described below. The controller 23 is configured with, for example, a microcomputer or a plurality of circuit blocks.

5 In the servo control apparatus 10, a control range is determined in accordance with the transfer function of the actuator and/or the detection sensitivity of the error detectors including the optical system such that the servo does not get out of place even though a disturbance in the servo system such as wobbling
10 rotation of the disc occurs. Gain characteristics and phase characteristics are set so that the system operates with stability within the range. In particular, equalization characteristics are determined so as to secure a sufficient phase margin in the required range of the servo system. More specifically,
15 equalization is performed so as to obtain a sufficient phase margin in the frequency range where the gain characteristics of an open-loop transfer function become 0dB. Equalization for focus servo, for example, is performed so as to obtain a sufficient phase margin within the frequency range of several hundred hertz to
20 several kilohertz.

Fig. 5 shows the configuration of the equalizer 17 in the embodiment. The tracking error signal TE and the focus error signal FE extracted in the signal processing circuit 15 are supplied to a proportion/differentiation gain multiplier (APD) 31 to be
25 multiplied by a coefficient bearing a predetermined gain. The multiplied error signals are supplied to a proportion/differentiation compensator 32 so as to undergo phase

compensation.

The proportion/differentiation compensator 32 is composed of a filter which can shift the phase of an input signal. More specifically, for example, a digital filter of the secondary IIR (infinite impulse response filter) and secondary FIR (finite impulse response filter) type can be used as shown in Fig. 5. The digital filter comprises coefficient multipliers 33A-33E, delay elements 34A-34D, and adders 35A-35B. The phase compensation characteristics can be changed by altering each of the coefficients 5 A0-A4 of the coefficient multipliers 33A-33E.

The error signal from the signal processing circuit 15 is also supplied to an integration gain multiplier (AI) 37. The integration gain multiplier (AI) 37 multiplies the supplied error signal by a set gain, and supplies it to an integrator 38. The 10 integrator 38 is so called a low-pass filter (LPF) including a primary IIR filter. In other words, the integrator 38 is an accumulating circuit for the low-pass components of error signals, and serves as a holding circuit for holding past low-frequency component of the error signals. An output signal from the 15 integrator 38 is added to an output signal from the above-mentioned proportion/differentiation compensator 32 at an adder 43, and the signal obtained from the adder is supplied to the driving portion 20 of the optical pickup 11 as drive signals (TD, FD).

Thus, when the integration gain of the integration gain 25 multiplier (AI) 37 increases, the output signal from the integrator 38 increases in magnitude, and the component, which is proportional to the current error, decreases in magnitude relatively. As a

result, the tracking performance to current disturbances (for example, an unexpected disturbance such as dropout of an RF signal due to a defect) deteriorates, making it possible to avoid the influence of the disturbance temporarily. If this operation is 5 continued, however, the focused state becomes impossible to be maintained due to a deterioration of the tracking performance to disturbances (for example, due to wobbling rotation of the disc) which should essentially be tracked. Thus, the integration gain and the proportional gain should be determined in respect to the 10 above-mentioned tracking performance to current disturbances.

As is shown in Fig. 5, the gains of the proportion/differentiation gain multiplier (APD) 31 and the integration gain multiplier (AI) 37 can be changed by a control signal from the controller 23. Similarly, the phase 15 characteristics of the proportion/differentiation compensator 32 can be changed by altering a coefficient of the coefficient multiplier (in the case shown in Fig. 5, coefficient A2, a secondary coefficient, of the coefficient multiplier 33C) by using a control signal from the controller 23. In the embodiment, the controller 20 23 generates control signals for the proportion/differentiation gain multiplier (APD) 31, the integration gain multiplier (AI) 37, and the proportion/differentiation compensator 32 based on the amplitude of the envelope signal of the RF read signal.

The generation of the envelope signal and the dropout 25 detection signal will be described below with reference to Figs. 6 and 7. As is shown in Fig. 6, the envelope signal (Fig. 7(b)) is extracted from an RF read signal (Fig. 7(a)) by an envelope

detector circuit in the signal processing circuit 15, and supplied to the controller 23. The envelope signal is compared with a predetermined discrimination level in a comparator circuit in the dropout detecting portion 21, and a dropout detection signal (Fig. 5 7(c)) having a predetermined voltage level (V_d) is generated. In the signal processing circuit 15, the generated envelope signal may be supplied to the controller 23 through a suitable low-pass filter (LPF).

The operation performed by the controller 23 for controlling gains and phases will be described with reference to the flowchart in Fig. 8 and to Figs. 9 and 10. It is determined whether or not any dropout is detected in the controller 23 (step S1). For example, it is determined whether or not a dropout has started by a rise (or fall) in the envelope signal. The amplitude of the envelope 15 signal is then sampled in response to the dropout detection signal (step S2).

As is shown in Fig. 9, the controller 23 generates a control signal for changing the gains of the proportional differentiation gain multiplier (APD) 31 and the integration gain multiplier (AI) 20 37 in accordance with the sampled amplitude. More particularly, when the envelope amplitude value (hereinafter referred to as "envelope level") is below a predetermined value (EL1), a control signal is generated so as to decrease the proportional gain (-6dB) and increase the integration gain (+6dB) because the reliability 25 of the error signal is low. On the other hand, when the envelope level exceeds another predetermined value EL2 ($\geq EL1$), the proportional and integration gains are not changed. In other words,

a control signal indicating the change value of 0dB is generated. When the envelope level is between EL1 and EL2, control is performed so as to change the change value of the proportional gain from -6dB to 0dB as the envelope level increases, and at the same time 5 gradually change the integration gain from +6dB to 0dB.

As described above, the controller 23 further generates a control signal for changing the secondary coefficient (A2) of the proportion/differentiation compensator 32 in accordance with the envelope level. More particularly, a control signal is generated 10 for changing the value of the coefficient so as to control transient phenomenon by increasing phase margin when the envelope level is below a first predetermined value (EL3), as is shown in Fig. 10. On the other hand, a control signal is generated to indicate that the phase is not to be changed when the envelope level exceeds 15 a second predetermined value EL4 (\geq EL3). In this manner, a control signal is supplied to the equalizer 17 so as to change the gain and phase in accordance with the envelope level (step S4).

It is then determined whether or not the dropout is continuing (step S5). When the dropout is continuing, the procedure goes 20 back to step S2 to sample the envelope amplitude, and to repeat the steps described above. When the dropout is terminated (i.e., when the dropout is disappeared), whether or not the control for changing the gain and phase is to be continued is determined (step S6). The procedure goes back to step S1 to repeat the above steps 25 when the changing control is to be continued. Control exits the process routine when the changing control is not to be continued. Thus, the gain and phase of the equalizer 17 are controlled in

accordance with an amplitude of the envelope signal during the period of time when dropout occurs as described above.

Although the embodiment has been described taking an example where both the proportional gain and integration gain are changed 5 simultaneously, only one gain can be changed. In that case, all that needs to be done is to change the integration gain relative to the proportional gain. The above-described change value of gains and phase margin is a mere example. It may be set to a suitable value in accordance with the servo system to be used.

10 As described above, stable high-precision servo control is realized by changing the gain characteristics and phase characteristics of the equalizer 17 in accordance with the amplitude of the envelope signal during the period when dropout occurs.

15 [Second Embodiment]

Fig. 11 is a schematic diagram of the configuration of an equalizer in the servo control apparatus 10 according to a second embodiment of the present invention. The difference between the embodiment and the first embodiment is that, as is shown in Fig. 20 11, the equalizer 17 is further provided with a proportion/differentiation gain multiplier (APD2) 51 and a second integration gain multiplier (AI2) 53 so that the gains of the multipliers can be changed by a second control signal from the controller 23.

25 The controller 23 controls the equalization characteristics of the equalizer 17 using a second control signal for changing the integration gain of the second integration gain multiplier

(AI2) 53 or the proportional gain of the second proportional differentiation gain multiplier (APD2) 51 in accordance with the change of an error signal in addition to the control signal for changing gains in accordance with the envelope level as described
5 in the first embodiment.

In this embodiment, a change amount or variance of an error signal (hereinafter, simply referred to as "error change") defined below is used in order to complement gain control by the envelope level.

10 Error change = integral value of error (over an angular section of rotation where a dropout occurs) - integral value of error (over the same angular section of rotation before the dropout occurs).

15 In more detail, an integrated or integral value is obtained for an error signal over a range or section of rotational angle (hereinafter, referred to as an angular section of rotation) on a track before a dropout occurs. An integral value is, then, obtained over the same angular section of rotation on a track where a dropout occurs. The error change is obtained by subtracting
20 the integral value for the angular section of rotation where a dropout occurs from the integral value before the occurrence of the dropout for the same angular section of rotation.

More specifically, for example, the difference between an integral value of the error signal in one period of the FG pulse
25 when dropout occurred and an integral value of the error signal in the same FG pulse period, i.e., in the same angular section on a different track as that of the former can be used. A drive

signal may be used instead of the error signal.

The error change can be generated in the controller 23 as described above. The generation process of the error change can be performed in circuit blocks shown in Fig. 12. After an error signal is converted to a digital signal in an analog/digital (A/D) converter 56, an integral value is generated by an integration circuit 57. The integral value is supplied to an input terminal on the L terminal of a selector 60 and to a subtracter 59. An output terminal of the selector 60 is connected to an FIFO (first-in first-out) memory 58. The output from the FIFO memory 58 is supplied to an input H terminal of the selector 60. A dropout detection signal is supplied to a control terminal of the selector 60. With such configuration, the selector 60 supplies the integral value supplied from the integration circuit 57 selectively to the FIFO memory 58 when the dropout detection signal is on the L level, i.e., when dropout is not detected. Or, the selector 60 supplies an output signal from the FIFO memory 58 selectively to the FIFO memory 58 when the dropout detection signal is on the H level, i.e., when a dropout is detected.

The FIFO memory 58 consists of N stages of memories. An FG pulse signal having N pulses/rotation of the disc is supplied to the FIFO memory 58 through the gate circuit 60. The content of the memory 58 is sequentially supplied to the subtracter 59 in response to the FG pulse signal. In other words, the output from the subtracter 59 is an integral value of the error signal in the current angular section of rotation minus an integral value of the error signal in the same angular section of rotation on

a different track. The above configuration is designed so that the supply of an integral value of the error signal to the FIFO memory 58 is forbidden and data in the FIFO memory 58 is not updated when a dropout is detected. Consequently, the latest integral
5 value before a dropout is detected is stored in the FIFO memory 58.

The procedure of control operation performed by the controller 23 is similar to that in the first embodiment except that, in addition to the first control signal for changing gains
10 in accordance with the envelope level, a second control signal for changing gains in accordance with the error change is supplied to the second proportion/differentiation gain multiplier (APD2) 51 and the second integration gain multiplier (AI2) 53 in the equalizer 17. More particularly, as is shown in Fig. 13, the
15 controller 23 increases in the negative direction the change of the proportional gain as the absolute value of the error change increases when the error change is less than a first predetermined value (EV1) in the negative region (in the case shown in Fig. 13, from 0dB to -0.2dB). The controller 23 increases the change of
20 integration gain (from 0dB to 0.4dB) as well as decreases the proportional gain, thus increases the integration gain. Specifically, it is assumed that a normal error signal cannot be obtained due to the dropout (i.e., the error signal is assumed
25 to be nearly 0). Therefore, control is maintained so as not to track the error signal affected by the dropout by increasing the integration gain as well as by decreasing the proportional gain. On the other hand, the change of proportional gain is increased

(from 0dB to 0.4dB) as the error change increases when the error change exceeds a second predetermined value (EV2) in the positive region. More specifically, the change of integration gain is increased in the negative direction (i.e., from 0dB to -0.4dB) 5 as the proportional gain is increased, thus the integration gain is decreased. In other words, control is considered to be greatly deviated from the target state due to disturbances caused by the rotation of the disc and the like when an error change exceeds the second predetermined value (EV2) in the positive region. Thus, 10 the integration gain is decreased so as to improve the tracking performance of the servo control apparatus to the disturbances at the same time as the proportional gain is increased. No compensation of the proportional gain and the integration gain is performed (i.e., 0dB) when the error change is between the first 15 predetermined value (EV1) and the second predetermined value (EV2). The change of the above gains can be suitably selected in accordance with the servo system or the kind of the disc to be used.

As described above, more stable high-precision servo control can be achieved by adding gain compensation to gain control by 20 the envelope level. Although a description has been made of an example where the gains of the second proportion/differentiation gain multiplier (APD2) and the second integration gain multiplier (AI2) are adjusted so as to compensate the gain of the equalizer 17, the present invention is not limited to the case but applicable 25 to various cases. For example, the control signal may be determined based on the above error change for changing the characteristics of the proportion/differentiation gain multiplier (APD) 31, the

integration gain multiplier (AI) 37, and the proportion/differentiation compensator 32 in the equalizer 17 in Fig. 5, which is used for illustrating the first embodiment. Another possible design is, as shown in Fig. 14, to change the 5 proportional gain or the phase characteristics of an equalizer having no integration gain multiplier (AI) 37.

As mentioned above, the characteristics of the equalizer 17 are adjusted by comparing the error change at the position on the track (i.e., angular section of rotation) where a dropout 10 occurred with that in the same angular section on the track before the dropout occurred. Accordingly, servo control can be stabilized while a dropout is occurring even though there is a defect at a certain region over a plurality of tracks to cause the dropout of an RF signal. In addition, the transient phenomenon 15 after the disappearance of the dropout can be controlled to realize stable high-precision servo control.

[Third Embodiment]

Fig. 15 is a block diagram illustrating the configuration of a servo control apparatus 10 according to a third embodiment 20 of the present invention. In order to simplify the description, the major part of the configuration of the servo control apparatus 10 is shown in circuit blocks.

In the embodiment, a focus error signal from a focus error detector 61 is supplied to the equalizer 17 through a switch 62, 25 and at the same time, the error value indicated by the focus error signal is supplied to and held in an error value holder 63. The switch 62 selectively supplies a focus error signal from the focus

error detector 61 or the error value from the error value holder 63 to the equalizer 17 in response to a logical signal from a logical AND circuit 64. The switch 62 takes the AND of a dropout detection signal from a comparator 66 and an error change discrimination signal from a discriminator 68 for discriminating whether an error change is below a predetermined value. In other words, the logical AND circuit 64 sends out a signal of H level when a dropout is detected and the error change is below a predetermined value, and causes the error value from the holder 63 to be supplied to the equalizer 17. A control signal from the controller 23 is supplied to a memory 73, and an error value corresponding to the angular section of rotation where the dropout occurred is output from the memory 73 to the holder 63 as a "hold value".

Although a description has been given of an example wherein the error value held is outputted from the memory 73 only when the error change is less than a predetermined value. The held error value may be supplied to the equalizer 17 when a dropout is detected.

The configuration mentioned above makes it possible to hold the servo control value for an angular section of rotation on a track where a dropout occurred to the value for the same angular section of rotation on a different track before the dropout occurred so as to realize stable high-precision servo control.

[Fourth Embodiment]

Fig. 16 is a block diagram illustrating the configuration of a servo control apparatus 10 according to a fourth embodiment of the present invention. In the same manner as for the third

embodiment, the major part of the configuration of the servo control apparatus 10 is shown in individual circuit blocks.

The difference between this embodiment and the above third embodiment is that the equalization characteristics of the 5 equalizer 17 are changed in response to a dropout detection signal and an error change discrimination signal. A logical AND operation of a dropout detection signal and an error change discrimination signal are performed in the logic AND circuit 64, and the logical AND signal is supplied to the switch 62.

10 Specifically, the gain of an amplifier 71 in the equalizer 17 is selectively switched to a low gain value during the period when a dropout is detected and the error change is below a predetermined value as shown in Fig. 16.

A modification of the embodiment is shown in Fig. 17, wherein 15 the equalization characteristics of the equalizer 17 are changed in response to a dropout detection signal and an error change discrimination signal. The phase compensation value of the proportion/differentiation compensator 32 in the equalizer 17 is selectively switched to a second phase compensation value during 20 the period when a dropout is detected and the error change is less than a predetermined value in the embodiment.

[Fifth Embodiment]

Referring now to Figs. 18-20, a description is made for the servo control operation performed by a servo control apparatus 25 10 according to a fifth embodiment of the present invention. The configuration of the servo control apparatus 10 and the equalizer 17 is similar to that shown in Figs. 4 and 5.

In the embodiment, the equalization characteristics of the equalizer 17 including the gain characteristics and phase compensation characteristics are changed during and after the occurrence of a dropout in order to control the transient phenomenon 5 caused in an error signal due to the occurrence of the dropout. The procedure of the control operation is described in detail below.

Fig. 18 is a flowchart of a focus-error-hold operation to be performed by the controller 23. Fig. 19 is a flowchart of a procedure for changing the equalization characteristics of the 10 equalizer 17. The procedures shown in the flowcharts are performed in parallel with each other. A time chart for illustrating the change of the equalization characteristics of the equalizer 17 is shown in Fig. 20.

Referring now to Figs. 18 and 20, it is determined whether 15 or not a dropout is detected by the controller 23 (step S11). For example, it is determined whether a dropout has started by the rise (or fall) of an envelope signal. A focus error value FE is then held to a predetermined value (for example, to 0) in response to the dropout detection signal. At the same time, the timer starts 20 time measurement (step S12). During the dropout generation period, a focus error shows a transient oscillation, so the focus-error-hold operation controls the drive signal and stabilizes the operation of the optical pickup.

It is then determined whether or not the duration of a dropout 25 has reached a predetermined time (T_{dd}) (step S13). When the duration of the dropout has reached the predetermined time (T_{dd}), the focus-error-hold operation is released (step S15). This is

to prevent servo from becoming unstable because the focus-error hold time being prolonged more than is required may cause the servo to become unstable.

In step S13, if the duration has not reached the predetermined time (T_{dd}), it is determined whether or not the dropout has terminated (step S14). If the dropout has not terminated, the procedure goes back to step S13. On the other hand, if the dropout has terminated, the procedure goes on to step S15, and the focus-error-hold operation is released.

The presence of a control signal indicating the termination of servo control is discriminated (step S16) after the focus-error-hold operation is released in step S15. The procedure goes back to step S11 to repeat the above-mentioned procedures when servo control is to be continued. On the other hand, the current routine exits when servo control is to be terminated.

Referring now to Figs. 19 and 20, a procedure for changing the equalization characteristics of the equalizer 17 is described. The equalization characteristics of the equalizer 17 are set to normal gain and phase characteristics, i.e., to the characteristics when no dropout occurs (EQ1) (step S21) by the controller 23. It is then determined whether or not a dropout is detected (step S22).

In response to the dropout detection signal, the equalization characteristics are changed to the equalization characteristics to be used in a dropout period (EQ2). At this time, it is preferable to increase the phase margin, and to change the phase compensation characteristics so as to obtain the maximum phase margin.

Increased phase margin makes the convergence of an error signal

waveform and also the rise of an RF signal faster so as to perform stable servo control. The change of phase compensation characteristics and gains can be performed by changing the coefficient value of the proportion/differentiation compensator 5 32 and an integration gain, for example. The change of a coefficient value may be performed by table read/write operation in the controller 23.

It is then determined whether or not the dropout has terminated (step S24). When the termination of the dropout is 10 discriminated, it is determined whether or not a predetermined time (Tde) has passed since the termination of the dropout (step S25). If the predetermined time (Tde) has passed, a coefficient value is calculated (step S26) for changing the equalization characteristics of the equalizer 17, and the characteristics change 15 is performed based on the calculated coefficient value (step S27). It is then determined whether or not the change of the equalization characteristics from EQ2 to EQ1 has been completed by the change of the coefficient value (step S28). If it has not been completed, the procedure goes back to step S26. As is shown in Fig. 20, the 20 characteristics change is gradually performed from EQ2 to EQ1 by carrying out steps S26-S28 repeatedly.

When the change of the equalization characteristics is completed in step S28, the presence of a control signal indicating the termination of servo control is discriminated (step S29). If 25 servo control is to be continued, the procedure goes back to step S22 to repeat the above-mentioned procedures. On the other hand, the current routine exits when servo control is to be terminated.

As described above, the convergence of an error signal waveform is made faster and the transient phenomenon after the occurrence of a dropout is controlled by changing the equalizer's characteristics in response to the occurrence and termination of 5 a dropout or in response to the time which elapsed since the occurrence and termination of a dropout. Thus, stable high-precision servo control is realized.

Although a description has been given of an example in which the focus-error hold value is set to 0, a rotation component or 10 a boost component may be used.

As the various embodiments mentioned above are for exemplification, their application in suitable combinations is possible. Similarly, each of the numerical values shown in the above embodiments is given only illustrative. The values may be 15 determined properly in accordance with, for example, the servo system, the kind of disc, or the like to be used.

[Effect of the Invention]

From the above description, it is clear that the present invention provides a servo control apparatus which can achieve 20 stable high-precision servo control with a high defect treatment performance.

[Document Name] ABSTRACT

[Abstract]

[Object]

It is an object of the present invention to provide a servo
5 control apparatus which has a high capability of addressing defects
and performing stable servo control during the period of time when
a dropout occurs and after the termination of the dropout.

[Measure taken to attain the Object]

An apparatus includes an error signal extracting portion
10 for extracting an error signal from a read signal, the error signal
indicating a deviation from a servo target value of the optical
pickup; an equalizer including a phase compensator for equalizing
the error signal by the phase compensator to generate a drive signal;
a driving portion for changing the servo position of the optical
15 pickup in response to the drive signal; a dropout detecting portion
for extracting an envelope signal from the read signal to detect
a dropout of the read signal; and a controller for changing an
equalization characteristics of the equalizer in accordance with
an amplitude of the envelope signal in the portion of the dropout.
20 The equalizer includes an integrator for integrating the error
signal to generate an error integration signal and an adder for
supplying an added signal of an error proportional signal which
is proportional to the error signal and the error integration signal
to the driving portion as the drive signal; wherein, when the
25 amplitude of an envelope signal in the portion of the dropout is
less than a predetermined value, the controller decreases the gain
of a proportion/differentiation gain multiplier and increase the

gain of a integration gain multiplier.
